The hole injection capability is essentially important for GaN-based vertical cavity surface emitting lasers (VCSELs) to enhance the laser power. In this work, we propose GaN-based VCSELs with the p-AlGaN/p-GaN structure as the p-type hole supplier to facilitate the hole injection. The p-AlGaN/p-GaN heterojunction is able to store the electric field and thus can moderately adjust the drift velocity and the kinetic energy for holes, which can improve the thermionic emission process for holes to travel across the p-type electron blocking layer (p-EBL). Besides, the valence band barrier height in the p-EBL can be reduced as a result of usage of the p-AlGaN layer. Therefore, the better stimulated radiative recombination rate and the increased laser power are obtained, thus enhancing the 3 dB frequency bandwidth. Moreover, we also investigate the impact of the p-AlGaN/p-GaN structure with various AlN compositions in the p-AlGaN layer on the hole injection capability, the laser power, and the 3 dB frequency bandwidth.

Keywords: GaN-based VCSEL; hole injection; laser power; modulation response.

1. Introduction

Due to the advantages of low threshold current, single longitudinal mode output, easy process for packaging, wafer level testing, and circular output beams[1], vertical cavity surface emitting lasers (VCSELs) have shown tremendous application potential in data communication, retinal scanning displays, medical laser, high density optical storage, printing and optical scanners, etc.[2–4]. Since the first, to the best of our knowledge, room-temperature electrically injected GaN-based VCSEL was achieved in 2008[5], great efforts have been made to achieve better lasing performance for GaN-based VCSELs[6–8]. However, the development of GaN-based VCSELs still faces quite a few challenges. One of the obstacles that hinder the lasing performance is lateral optical mode confinement. Lateral optical mode confinement can be realized by using the buried SiO2 layer below indium-tin-oxide (ITO), where the design can also reduce the internal loss[9]. However, an even easier method to achieve the lateral mode confinement is locally varying the cavity length, and therefore a nano-height cylindrical waveguide structure has been reported[10]. Another obstacle that hinders the improvement for the laser power is low hole injection, which arises from the current crowding effect at the aperture periphery and the hole blocking effect by the p-AlGaN electron blocking layer (p-EBL). For the purpose of shaping the current paths for VCSELs, a tunnel-junction VCSEL and a VCSEL with a p-GaN/n-GaNP-GaN structured current spreading layer are proposed to increase the current injection into the aperture[11,12]. Besides, the AlGaN/GaN multiple-quantum-barrier structured p-EBL and Al composition-graded p-EBL have been reported, which can promote the hole injection efficiency by reducing the valence band barrier height of p-EBL[13,14].

Besides shaping the current flow paths and reducing the valence band barrier height, the hole injection efficiency can also be effectively improved by increasing the kinetic energy of the holes. Therefore, in this work, we propose a p-AlGaN/p-GaN structure as the p-type hole injection layer [see Fig. 1(b)]. The negative polarization induced sheet charges at the p-AlGaN/p-GaN interface enhance the electric field intensity in the p-GaN layer, which will increase the drift velocity and kinetic
energy of the holes [see Fig. 1(b)]. Besides, the usage of the p-AlGaN layer can also reduce the valence band barrier height in the p-EBL [see Figs. 1(a) and 1(b)]. Therefore, the holes can easily cross over the valence band of the p-EBL after obtaining more kinetic energy from the p-AlGaN/p-GaN structure, which results in the increased hole concentration within the multiple quantum wells (MQWs). Then, the improved hole concentration will correspondingly enhance the stimulated radiative recombination rate and then the laser power for VCSELs. Moreover, the enhanced stimulated radiative recombination rate indicates the reduced differential carrier lifetime, and this helps to increase the 3 dB frequency bandwidth. Detailed analysis will be discussed subsequently.

2. Device Structure

We design different GaN-based VCSELs to better explore the impact of the p-AlGaN/p-GaN structured p-type hole injection layer on the hole injection capability. The conventional GaN-based VCSEL is designed for comparison, as shown in Fig. 1(a), which is composed of a 28-pair AlN/GaN bottom distributed Bragg reflector (DBR), a 7 μm-thick cavity, and a seven-pair SiO2/Ta2O5 top DBR. The λ is the targeted lasing wavelength of 450 nm. The device structure between the bottom and top DBRs consists of an n-GaN layer (880 nm) with the Si doping concentration of 5×10^{17} cm^{-3}, five pairs of In0.21Ga0.79N/GaN (3 nm)/GaN (4 nm) MQWs, a p-Al0.2Ga0.8N (20 nm) p-EBL, a p-GaN layer (240 nm), and a 20-nm-thick ITO current spreading layer. Meanwhile, a 20-nm-thick SiO2 is buried below ITO to obtain lateral optical and electrical confinement due to the small refractive index and insulation characteristics. The radii of the SiO2 aperture and the mesa of the VCSELs are designed to be 4 μm and 6.5 μm, respectively. The conventional VCSEL is called VCSEL A. The proposed VCSELs (VCSELs B1 to B3) are identical to VCSEL A except that the 240-nm-thick p-GaN hole injection layer is replaced by the p-AlxGa1−xN/p-GaN (50 nm/190 nm) structure in Fig. 1(b). Considering the Mg ionization rate and the Poole–Frenkel effect, the free hole concentration in both the p-AlxGa1−xN and p-GaN layers is set to 8×10^{17} cm^{-3}. The detailed AlN composition (x) in the p-AlxGa1−xN layer for VCSELs B1 to B3 can be found in Table 1.

Holes will encounter a large valence band offset (φ) between the p-EBL and the p-GaN with the value of 159.10 meV for VCSEL A [see Fig. 1(a)]. However, such valence band offset can be reduced by using the p-EBL/p-AlxGa1−xN structure [see Fig. 1(b)]. The p-AlxGa1−xN/p-GaN structure enables the storage of the electric field due to the polarization feature for this junction, and the electric field in the p-GaN layer will increase the hole energy, which is able to suppress the hole blocking effect by the p-AlxGa1−xN/p-GaN interface [see Fig. 1(b)]. As a result, a compromised effect of the descending hole concentration in the p-AlxGa1−xN layer and the reduced valence band offset at the p-EBL/p-AlxGa1−xN interface can decrease the hole blocking effect by the p-EBL. Correspondingly, the hole injection efficiency into the MQWs can be enhanced for the proposed VCSELs.

To better illustrate the aforementioned point of view, in this work, the Photonic Integrated Circuit Simulator in 3D (PICS3D) is used to investigate the impact of the p-AlGaN/p-GaN structure on the GaN-based VCSELs, which contains various equations such as Poisson’s equation, rate equation, current continuity equation, carrier transport equation, and complex wave equation [15]. The Auger recombination is considered by setting the Auger recombination coefficient to 1.4×10^{-43} m^{6}\cdot s^{-1}[16]. Considering the non-radiative recombination occurring at defects, the Shockley–Read–Hall (SRH) lifetime is set to be 1×10^{-8} s [16]. In the meantime, we also consider a 40% polarization level for the [0001] oriented VCSEL structure [17,18]. The band-offset ratios for the InGaGaN/GaN and GaN/AlGaN heterojunctions are set to 0.70/0.30 and 0.50/0.50, respectively, which defines the ratio of the conduction band offset and the valence band offset [19,20]. The polarization level of 40% is assumed in our model for the GaN/AlGaN heterojunction [21,22]. The average optical loss for the p-GaN layer, the p-EBL, the MQWs, and the n-GaN layer in our modes is set to be 1000 m⁻¹.

3. Results and Discussion

To probe the impact of the p-AlxGa1−xN/p-GaN hole injection layer on the hole injection capability, we firstly demonstrate the longitudinal hole concentration profiles in the MQWs region for VCSEL A and VCSELs B1 to B3 in Fig. 2(a). It shows that the hole concentration for VCSELs B1 to B3 is higher than that for VCSEL A. It is worth noting that the hole concentration in the central aperture for VCSELs B1 to B3 is not remarkably

increased when compared with VCSEL A, and this means that the current spreading effect for VCSELs B1 to B3 shall be further improved [see Fig. 2(b)]. However, this makes sense such that GaN-based VCSELs with lateral injection current schemes are challenged by the worse current spreading effect [23]. Once the p-AlGaN/p-GaN structure is adopted, the vertical hole injection is significantly promoted before the holes can be laterally spread. However, the overall hole concentration in the active region can be increased by generating high-order laser beams. Then, we present the injection hole current for the three devices in Fig. 2(c), which shows that the hole injection current is increased greatly for VCSELs B1 to B3 when compared with VCSEL A. Therefore, the total laser power is enhanced for VCSELs B1 to B3 in Fig. 2(d). Meanwhile, Fig. 2(d) also indicates that the threshold current slightly decreases for VCSELs B1 to B3 due to the improved hole injection capability. However, if we compare VCSELs B1, B2, and B3, we find that the hole concentration, laser power, forward voltage, and hole injection current increase first and then decrease as the AlN composition of the p-AlGa1−xN layer increases. Therefore, the variations in the hole concentration, laser power, forward voltage, and hole injection current for VCSELs B1, B2, and B3 are closely associated with the p-AlGa1−xN/p-GaN structure.

As mentioned previously, the enhanced hole concentration in the MQWs and the improved laser power are attributed to the promoted hole injection capability, which is tentatively attributed to the electric field in the p-AlGa1−xN/p-GaN hole injection layer. Therefore, we present the electric field profiles in the p-AlGa1−xN/p-GaN heterojunction for VCSELs A, B1, B2, and B3 to further probe the impact of the p-AlGa1−xN/p-GaN hole injection layer on the hole transport, as shown in Fig. 3(a). We can clearly see that the electric field intensity in the p-GaN region for VCSEL A is smallest among the discussed VCSELs, especially at the p-AlGa0.84N/p-GaN interface in Fig. 3(a). The smallest electric field intensity is attributed to the absence of negative polarization induced sheet charges at the p-AlGa1−xN/p-GaN interface for VCSEL A. Therefore, the electric field in the p-GaN layer only arises from the applied bias. Meanwhile, we find that the electric field intensity in the p-GaN region becomes stronger with AlN composition in the p-AlGa1−xN layer increasing to 0.02, 0.10, and 0.16, respectively. Hence, the p-AlGa1−xN/p-GaN enables the storage of the electric field in the p-GaN layer. However, it is worth noting that the electric field intensity in the p-AlGa1−xN layer is weaker for VCSELs B1 to B3 when compared with that for VCSEL A. Therefore, it is important to consider the compromised effect of the electric fields in p-AlGa1−xN and p-GaN layers. By following $W = \int_0^L E_{\text{field}}dx$ ($W$, $L$, and $E_{\text{field}}$ represent the obtained total energy for the holes, the integration range, and the electric field, respectively), we can get the energy that the holes obtain from the p-AlGaN and p-GaN layers, where the values are −1.53 eV, −1.64 eV, −1.86 eV, and −1.76 eV for VCSELs A, B1, B2, and B3, respectively. Hence, the optimized VCSEL B2 with the p-Al0.10Ga0.90N structure can properly increase the hole energy to promote the hole injection. However, the comparison among VCSELs B1, B2, and B3 shows that when the AlN composition in the p-AlGa1−xN layer increases to 0.16, the electric field intensity in the p-GaN region for VCSELs B1 and B3 becomes weaker than that for VCSEL B2. If we refer to Fig. 2(b), we find that the forward bias for VCSEL B3 becomes smaller than that for VCSEL B2, which is likely due to the increased hole concentration in the p-GaN layer and enhances the electrical conductivity therein for VCSEL B3[24].

![Figure 3](image-url)  
**Fig. 3.** (a) Electric field profiles in the p-AlGa1−xN and p-GaN layers for VCSELs A, B1, B2, and B3, (b) hole concentration profiles in the p-EBL, p-AlGa1−xN, and p-GaN layers for VCSELs A, B1, B2, and B3, respectively. Data are calculated at the current of 20 mA.
B2, and B3, respectively. Therefore, the hole concentration in the p-AlGa1−xN layer is slightly lower for VCSELs B1 and B2 when compared with that for VCSEL A, although the valence band barrier height exists at the p-AlGa1−xN/p-GaN interface. However, the integrated hole concentration in the p-AlGa0.16N/p-GaN layer is the lowest in spite of the increased hole energy for VCSEL B3, which is likely attributed to the larger valence band barrier height for the p-AlGa0.16N/p-GaN interface, such that more holes are confined in the p-GaN layer. Therefore, there is a tradeoff between the hole acceleration effect and the hole blocking effect for the p-AlGa1−xN/p-GaN design.

The other advantage for the proposed device is that the adoption of the p-AlGa1−xN layer can produce a p-EBL/p-AlGa1−xN junction, and such a junction helps to reduce the valence band barrier height when compared with the p-EBL/p-GaN junction. Thus, the hole injection capability in the MQWs from the p-AlGa1−xN layer can be enhanced. Then, we present the valence band profiles in the p-EBL/p-GaN, p-EBL/p-AlGa0.98N, and p-EBL/p-AlGa0.99N regions for VCSELs A, B1, B2, and B3 in Figs. 4(a)–4(d), respectively. According to Figs. 4(a)–4(d), we then demonstrate the valence band barrier heights of the p-EBL/p-GaN, p-EBL/p-AlGa0.98N, and p-EBL/p-AlGa0.99N junctions, which are 159.10 meV, 153.10 meV, and 153.10 meV, respectively. We can clearly see that the stimulated radiative recombination rate (Rstim) in the MQWs regions at the current of 20 mA for VCSELs A, B1, B2, and B3 is higher than that at the current level of 1 mA, such that all of the quantum wells can produce the stimulated recombin-

Fig. 4. Valence band profiles in the p-EBL and the p-AlGaN layers for (a) VCSEL A, (b) VCSEL B1, (c) VCSEL B2, and (d) VCSEL B3. Data are calculated at the current of 20 mA.

Up to now, we have realized that using the optimized p-AlGa1−xN/p-GaN structure as the hole injection supplier will be able to improve the hole injection capability and enhance the laser power. Nevertheless, this design of multiple junctions may increase the parasitic capacitance for VCSELs B1 to B3 and decrease the modulation response capability. Therefore, it is necessary to present the impact of the designed VCSELs with the p-AlGa1−xN/p-GaN structure on the 3 dB frequency bandwidth. The calculated frequency response characteristics are presented in Figs. 5(a) and 5(b) for VCSELs A, B1, B2, and B3 at the injection current levels of 1 mA and 20 mA, respectively. The insets of Figs. 5(a) and 5(b) demonstrate the 3 dB frequency bandwidth for the discussed VCSELs at the current levels of 1 mA and 20 mA, respectively. If we compare Figs. 5(a) and 5(b), we find that the 3 dB frequencies for all the discussed VCSELs are increased as the injection current increases. To better explain the variation trend of frequency response characteristics with the injection current increasing, we also show the stimulated radiative recombination rate (Rstim) in the MQWs region for the discussed VCSELs at the current levels of 1 mA and 20 mA in Figs. 5(c) and 5(d), respectively. We can clearly see that the stimulated radiative recombination rate in the MQWs region at the current of 20 mA for VCSELs A, B1, B2, and B3 is higher than that at the current level of 1 mA, such that all of the quantum wells can produce the stimulated recombin-

![Fig. 5.](image)

Fig. 5. Calculated small-signal modulation response at the current levels of (a) 1 mA and (b) 20 mA for VCSELs A, B1, B2, and B3. Insets of (a) and (b) show 3 dB frequency bandwidth at the current levels of 1 mA and 20 mA, respectively.
helps to increase the 3 dB frequency bandwidth. Therefore, Fig. 5(b) generally shows that the most increased laser power can maximize the 3 dB frequency bandwidth, which is due to the reduced differential carrier lifetime for VCSEL B2. Nevertheless, we also find that the 3 dB frequency bandwidth is the smallest for VCSEL B3 among the discussed VCSELS at the current of 20 mA, although the stimulated radiative recombination rate for VCSEL B3 is increased when compared with that for VCSELS A and B1. This is mainly because the larger parasitic capacitance can be produced when the higher AlN composition is utilized in the p-\(\text{Al}_x\text{Ga}_{1-x}\)N for VCSEL B3.

4. Conclusion

To summarize, we have proposed and systematically analyzed the impact of different p-\(\text{Al}_x\text{Ga}_{1-x}\)N/p-GaN structures as the hole supplier on the hole injection capability, the laser power, and the 3 dB frequency bandwidth for GaN-based VCSELS. By using the p-\(\text{Al}_x\text{Ga}_{1-x}\)N/p-GaN heterojunction, the increased local electric field is produced in the p-GaN layer, which is very useful for increasing the kinetic energy and the drift velocity for holes. Therefore, more holes can reach the p-\(\text{Al}_x\text{Ga}_{1-x}\)N layer. Meanwhile, the usage of the p-\(\text{Al}_x\text{Ga}_{1-x}\)N layer reduces the valence band barrier height in the p-EBL. As a result, the AlN composition for the p-\(\text{Al}_x\text{Ga}_{1-x}\)N layer helps to increase the 3 dB frequency bandwidth. Therefore, we believe that the proposed VCSEL structure in this work is very important for the device physics reported here and the device physics reported here is very important for the VCSEL community.
